YSO spectrum (300-2000 nm)

- UV-Optical excess emission → *accretion shock*
- H I & other permitted lines (HeI, CaI, CaII, FeI, NaI, ...) → *accretion columns, winds*
- Forbidden lines ([FeII], [OI], [SII], [NII], ...) → *winds, atomic jet diagnostics*
- NIR excess → *inner disk*
- Photospheric absorption features → *spectral type, veiling, abundances, v sin i*

with simultaneous coverage of the whole 350-2000 nm range

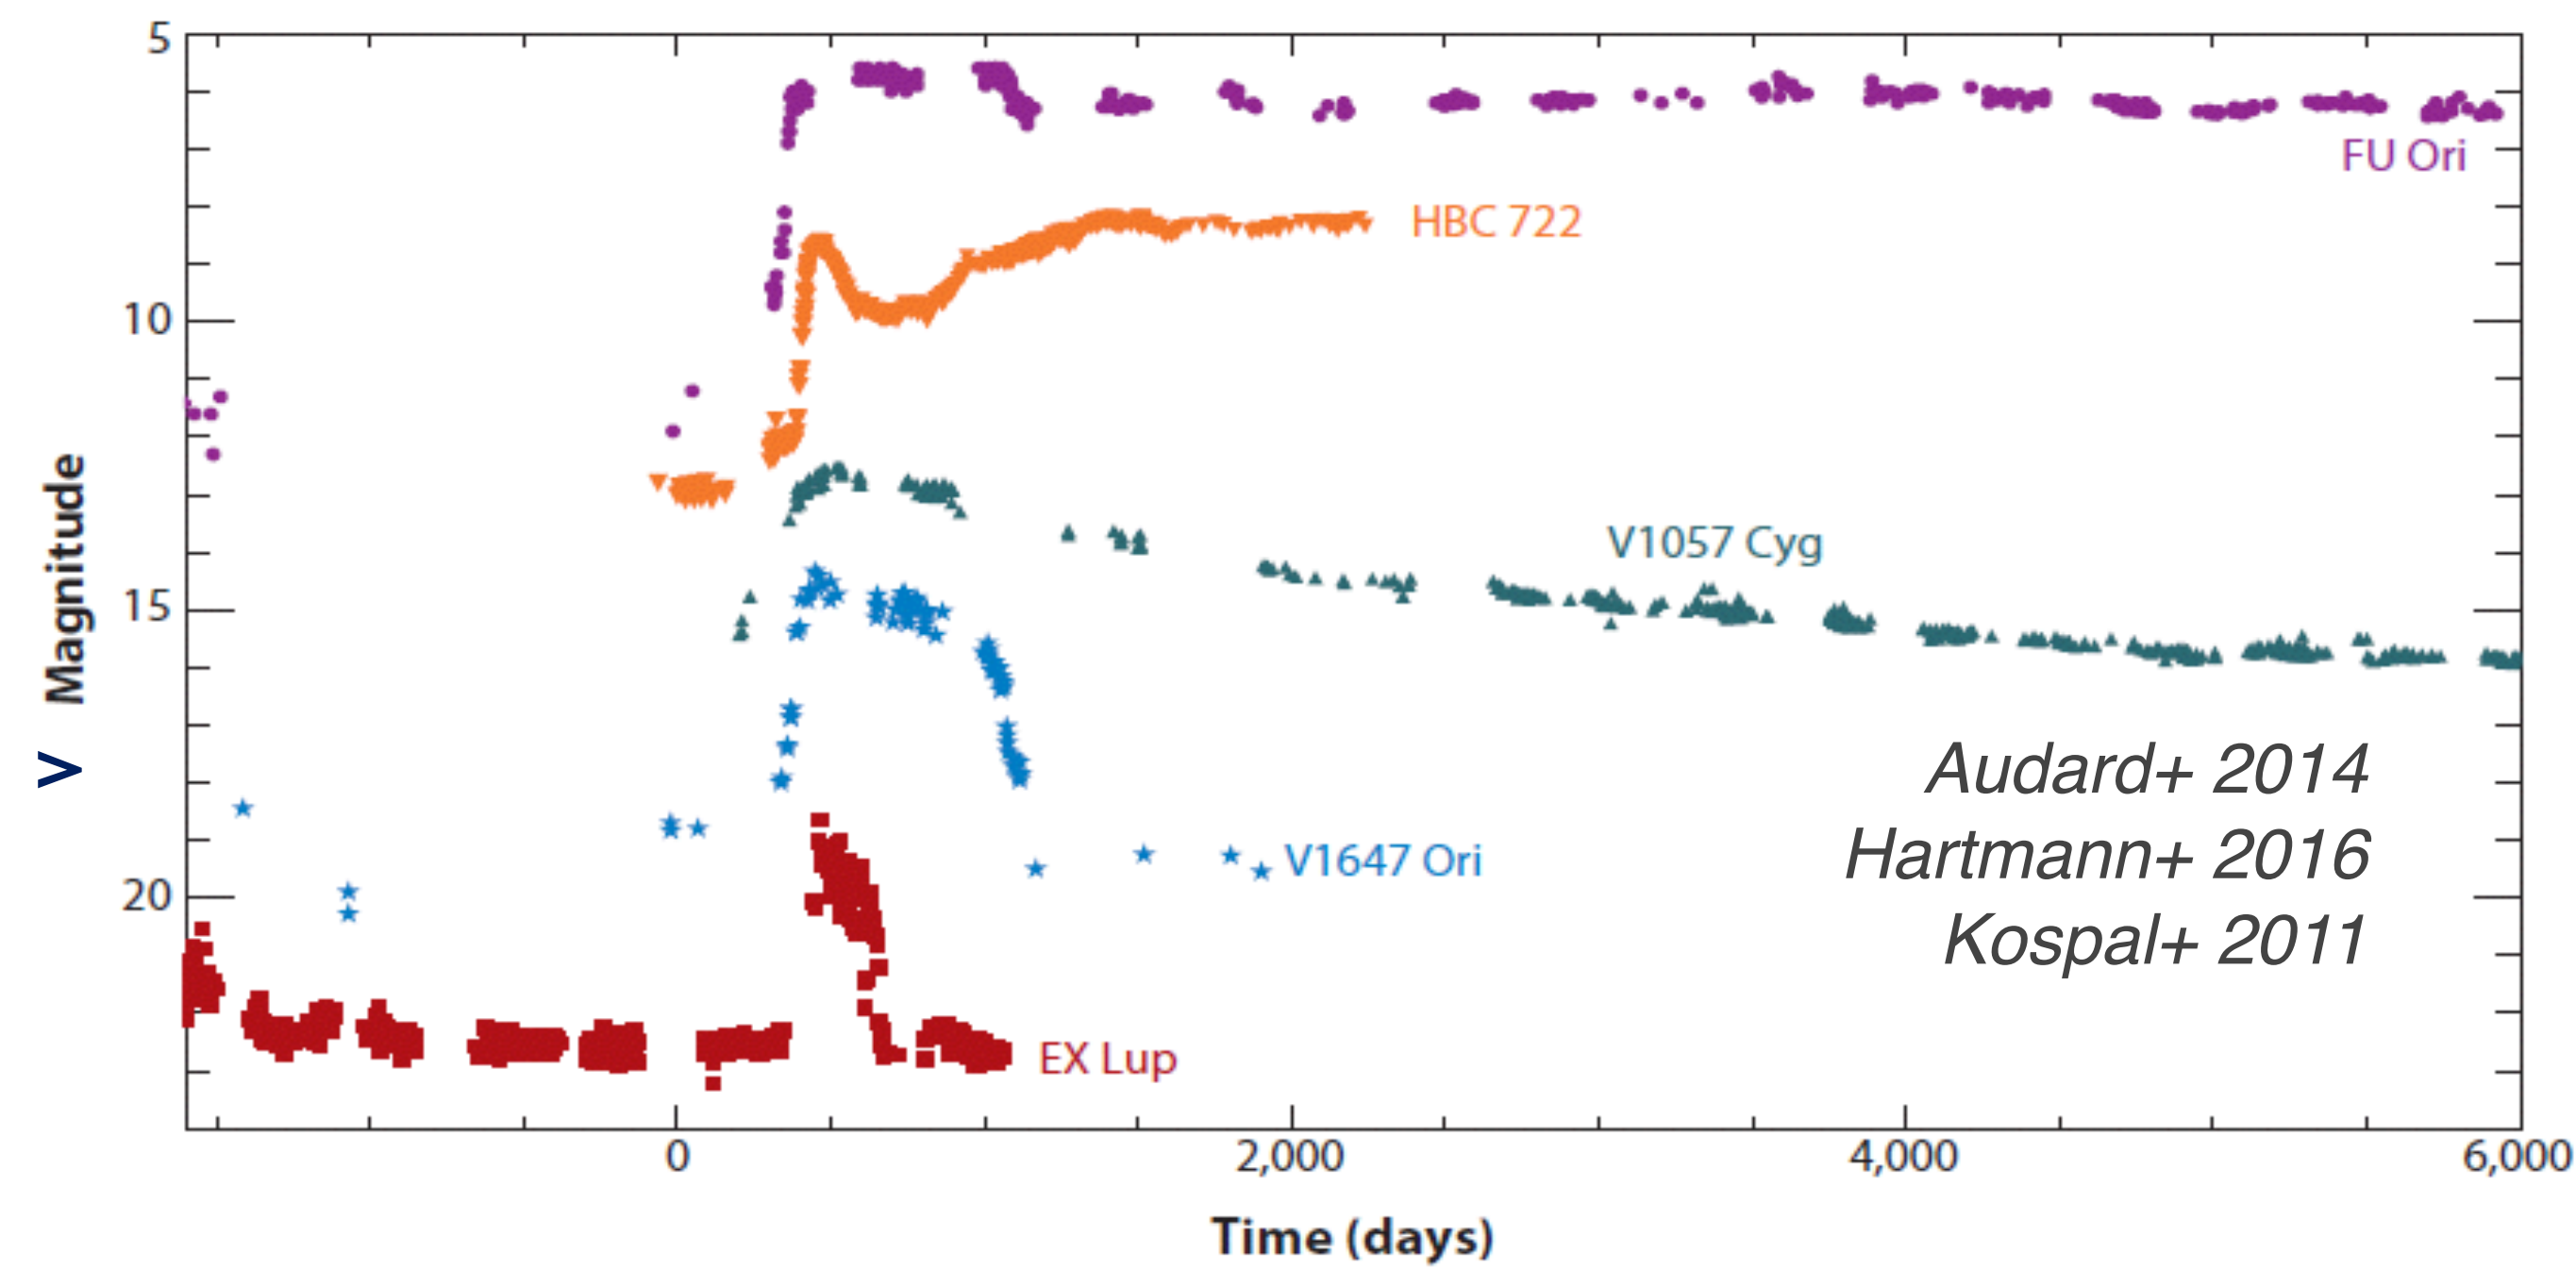

SOXS is the ideal instrument to fully characterize a YSO
→ *star, accretion, winds/jets, inner disk*

X-Shooter spectrum of RU Lup

Some pre-ms stars show recurrent accretion outbursts, classically detected in the optical: **FUor** and **EXor** events

| | ΔV | duration/recurrence | M_{acc} | obs |
|-------|------------|----------------------|--|------------------|
| EXors | 2-4 mag | months/several years | 10^{-5} - $10^{-7} M_{\text{sun}}/\text{yr}$ | emission lines |
| FUors | 5-7 mag | tens of years/? | 10^{-4} - $10^{-5} M_{\text{sun}}/\text{yr}$ | absorption lines |

Up to now sparse observations, poor monitoring → **only few tens of such objects are genuine eruptive variables**

Accretion evolution and outbursts

- Quasi-stationary accretion scenario:
→ low-mass stars form in 1-10 Myr with M_{acc} that declines from $10^{-4,-5}$ to $10^{-9,-10} M_{\text{sun}}/\text{yr}$
- But this scenario predicts much larger accretion luminosity than observed (**luminosity problem**)
- Assuming **short outbursts of enhanced accretion** like in EXors and FUors can solve the luminosity problem

- is the FUor/EXor phase a common stage for all YSOs?
- what is the outburst trigger mechanism?
- are there outbursts even in the embedded phase?

ToO SoXS proposal

**Photometric
trigger by
Gaia/LSST**

1. Mag variation alert (e.g. $\Delta\text{mag} > 2$)

2. Location in a star-forming region

3. SED typical of YSO (rising with λ)

4. Lightcurve (and colours)

**candidate
eruptive variables**

SoXS

1. examine spectral features (EXor/FUor)

2. derive parameters (star, M_{acc} , M_{loss})

**confirmed
outbursting
YSOs**

- Expected triggers : 10 objects per year
- Monitoring period of 6 months (8 observations).
- 80h of telescope time per year / ~ 5 nights per semester

SOXS characterization of EHB Padua variable stars in globular clusters

S. Zaggia, Y. Momany, L. Monaco, M. Gullieuszik, I. Saviane

Momany et al. (2020, *Nature Astronomy*, 4, 1091) have recently demonstrated that, at the end of their life, low-mass (like our Sun) suffer “A plague of huge magnetic Spots” during the so-called Extreme Horizontal Branch phase. Thus, a glimpse of the future evolution of our Sun. Stellar Spots trace their Magnetic activity.

The Sun is relatively cool (5778 K) & moderately old (4.6 Billion years) showing dark **spots** (typically Earth-sized).

EHB stars are twice older and 5-6 times hotter than our Sun. Close to their death, EHBs have half the Sun's radius but the spots are **bright** and are ~3000 times bigger (covering 25% of their surface). Thereby EHBs show stronger magnetic activity.

Having detected Stellar-Spots, especially giant ones, it is inevitable to detect the eruptive “face” of magnetic fields.

Solar Flares: sudden and unpredictable ejections of plasma & particles into outer space. Violent release of energy (10^{32} erg) in the vicinity of sunspots, lasting up to few hours.

We have detected **two superflare** events in EHB stars that are **10 million times more energetic** than typical solar flares, lasting for ~80 days. This is a new class of transient objects (we call **Padua** variables).

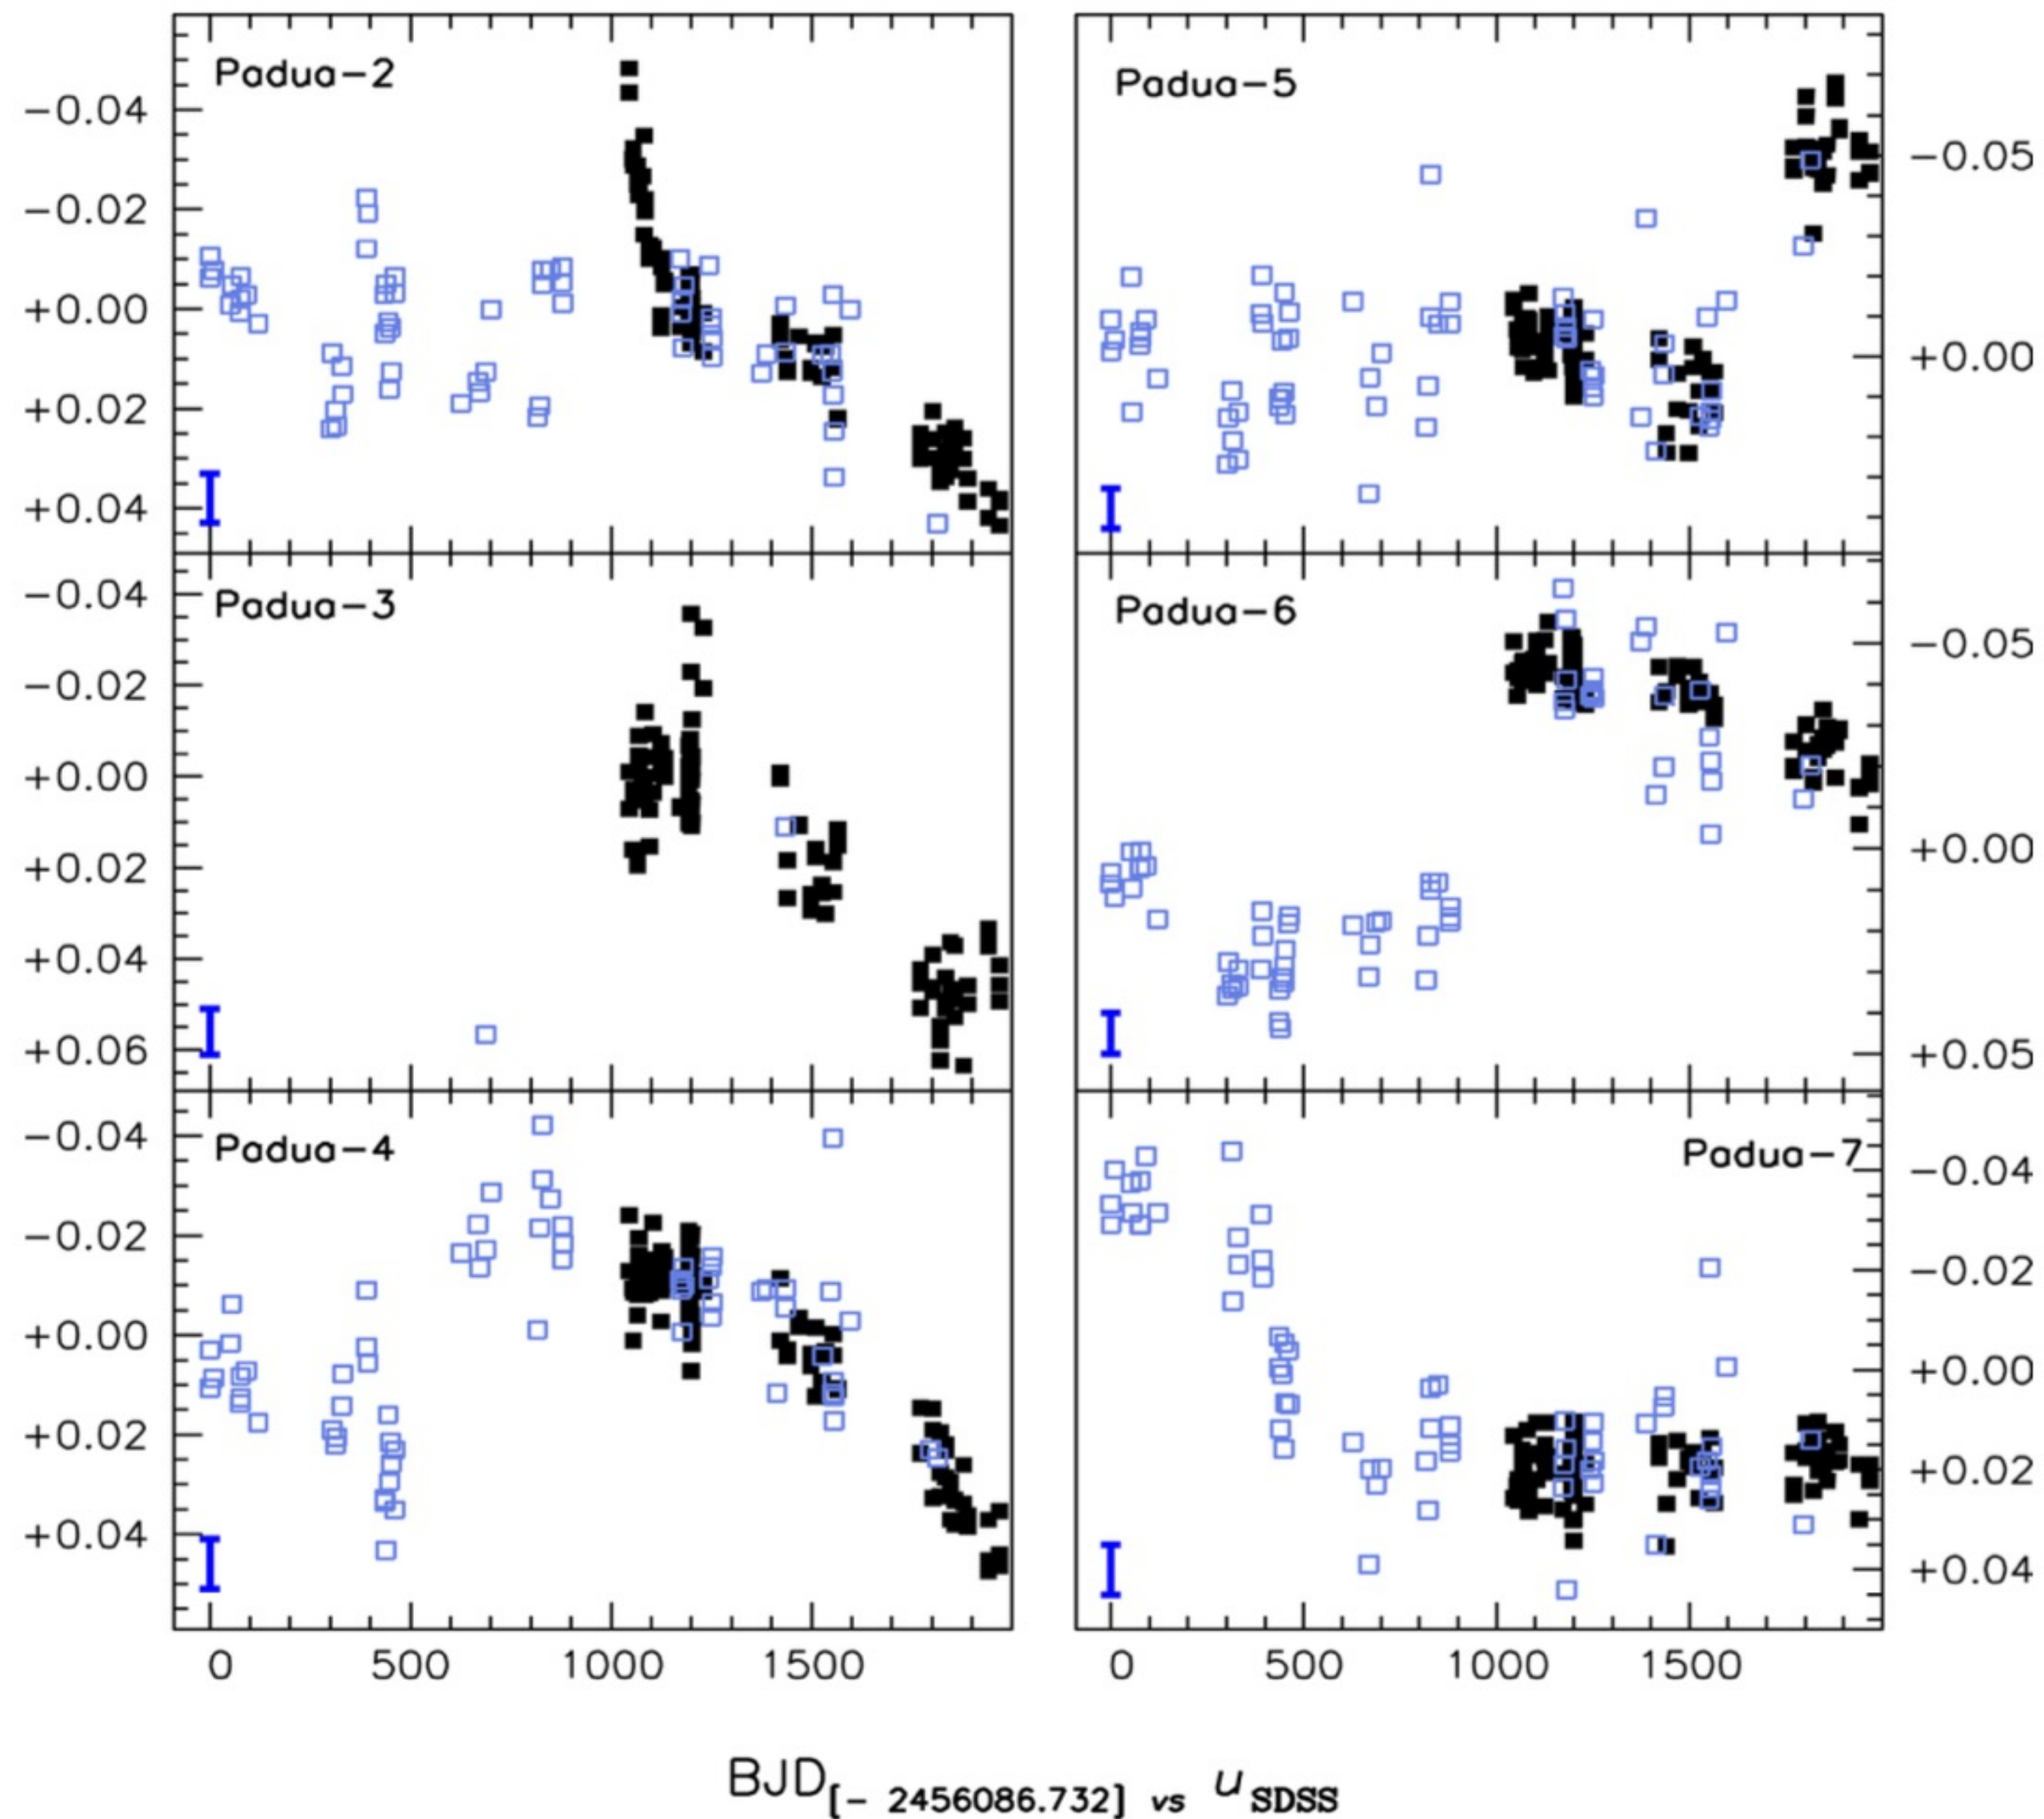

Six years monitoring of ~70 EHBs stars in the Globular Cluster NGC6752 allowed us to detect a full superflare event.

Padua-1 displayed almost constant luminosity for ~years, then had a mini-burst (~0.05 mag) that yet traces a violent release of energy (10^{40} erg) in these hot stars. Following the mini-burst, Padua-1 faded slightly, and returned to display a constant luminosity.

EHBs in Globular Clusters are certainly NOT binary systems, adding more interest to how they trigger the superflare events.

In particular, the long-duration of these mini but highly energetic bursts are likely to trace a rotating magnetosphere disk that outshines the star during the superflare event.

There are ~20 Globular Clusters in the Southern-hemisphere which posses ~50-100 EHB stars, each. We expect to detect at the very least 1 superflare event, per year, per cluster. However, continuous monitoring is mandatory (looking forward for the LSST).

We have missed the rising phase of the Padua-2 superflare event. Hence, continuous monitoring of these extremely peculiar EHB stars is important to trigger the ToO events.

Thanks to having detected/sampled the full mini-burst in Padua-1, we know that the luminosity “jumps” of these EHB stars (occurring on timescales of few hundred days) are preceded by a mini-burst (as can be seen also in Padua-2).

IN CONCLUSION

- RATE: We expect 1 event per year/per cluster.
- TRIGGERING: via active photometric monitoring either via VST on-going GTO programme or via LSST when available.
- NUMBERS: Active monitoring of the globular clusters with extended HB (30% of the ~100 visible from the South) will allow to have between ~30 events per year or 15 per semester.
- TIME: faintest EHB have magnitude $V \sim 20$, brightest $V \sim 16$. With 1h exposure we will be able to get a $S/N \sim 25$ and $S/N \sim 175$ respectively, in the UV/VIS part considering the high $T_{\text{eff}} \sim 20000$ K of these stars. After triggering we will need at least 1 spectrum per day first week and 1 every 3 days per 3 weeks for a total of 14h per event
- We will select only the more promising and the best and brightest events. In total we may expect to request 30 hours per semester.
