### ABSTRACT

We present very-high-energy gamma-ray observations of two binary black hole merger candidates, S240615dg and S241125n, performed with the Major Atmospheric Gamma Imaging Cherenkov (MAGIC) telescopes and the first Large-Sized Telescope of the Cherenkov Telescope Array Observatory's (CTAO LST-1). S240615dg was the best localized event of the fourth observing run of the LIGO-Virgo-KAGRA gravitational waves interferometers. S241125n was temporally and spatially coincident with a subthreshold short-duration burst detected with the *Swift*-Burst Alert Telescope (BAT), the *Swift*-X-Ray Telescope (XRT) and the *Einstein Probe* Follow-up X-ray Telescope (FXT). We observed the two events in stereoscopic mode, taking advantage of the improved sensitivity of joint MAGIC+LST-1 observations. No detection was achieved in the GeV-TeV gamma-ray band for any of the two sources. The unfavourable observing conditions of both events posed a challenge for a standard analysis and therefore a non standard analysis was necessary for both objects. Owing to the small localization area and the association with a GRB-like burst respectively, these events represented an unprecedented opportunity to study in details the electromagnetic emission from binary black holes merger events and, in particular, we discussed two theoretical models that predict a detectable gamma-ray emission and the possible future applications.

**Key words.** gamma rays: general – gravitational waves: individual S240615dg – gravitational waves: individual S241125n

### 1. Introduction

The first detection of a gravitational wave (GW) from a binary black hole (BBH) system merger was a historical breakthrough, marking the beginning of multimessenger astronomy as we know it today (Abbott et al. 2016). This led to a technological revolution in the field of gravitational wave astronomy (LIGO Scientific Collaboration et al. 2014, 2016, 2017, 2019, 2021a, 2021b, 2023, 2024). The LIGO Scientific Collaboration (LSC) and the Virgo Collaboration (Virgo Collaboration et al. 2015, 2016, 2017, 2019, 2021a, 2021b, 2023, 2024) and the KAGRA (LVK) Collaboration(s). Improvements in broadband sensitivity led to growth in the number of candidate GW events detected throughout the first four observing runs, achieving a total of 219 confirmed events so far<sup>1</sup>. Among them, 11 were observed during the first two observing runs (O1 and O2; Abbott et al. 2019b), 79 during the first and second half of the third run (O3a and O3b; Abbott et al. 2021a, 2023, 2024), and 129 during the first part of the fourth run (O4; Abac et al. 2024; The LIGO Scientific Collaboration et al. 2025)<sup>2</sup>, although numerous candidate events were made public via public alert systems. The vast majority of confirmed detections originate from BBH systems, with total masses in the range  $14 - 238 M_{\odot}$ , corresponding to chirp masses of  $7.4 - 225 M_{\odot}$  and distances up to 8.4 Gpc. Among the four observing runs, only two events were classified as binary neutron star (BNS; Abbott et al. 2017b, 2020a) and three neutron-star-black-hole binaries (NSBHs; Abbott et al. 2021b; Abac et al. 2024).

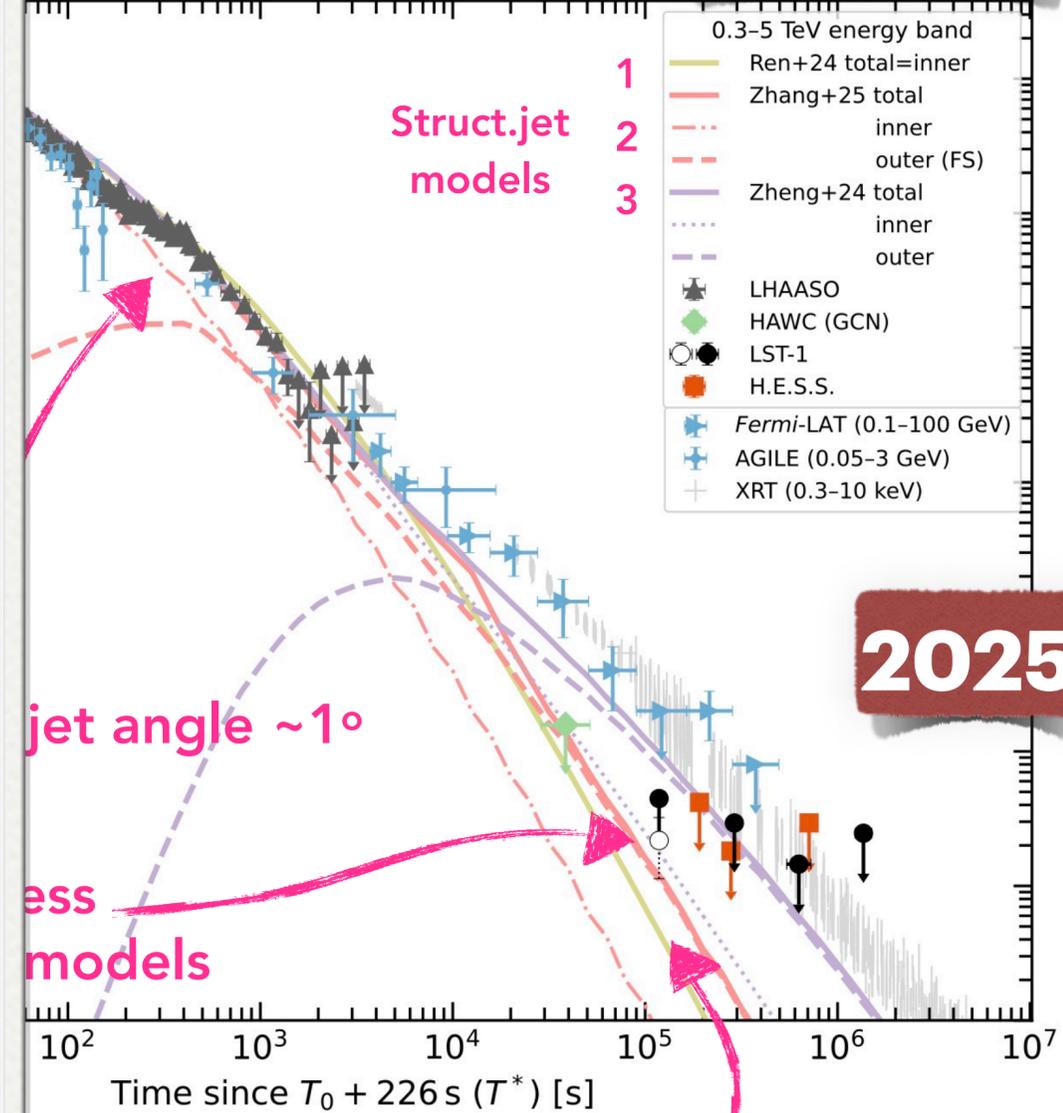

Detecting electromagnetic (EM) counterparts of GW events is one of the main challenges of current astrophysics and many facilities around the world and in space are dedicating their efforts to make this detection possible. The historical detection of GW170817 from a BNS merger by LIGO and Virgo (Abbott et al. 2017a) led to the discovery of a multi-messenger event (Abbott et al. 2017a) and the International Gamma-Ray Astrophysics Laboratory (INTEGRAL; Savchenko et al. 2017) space satellites, providing strong evidence of the association between BNS mergers and sGRBs (Abbott et al. 2017a). Soon after the initial trigger, an extensive follow-up campaign was launched across the entire EM spectrum leading to the detection of the optical/NIR counterpart AT 2017gfo, followed by X-rays and radio detection of the GRB afterglow (Abbott et al. 2017 and references therein). The afterglow was extensively followed in the gamma-ray band, spanning over 10 orders of magnitude in energy by space and ground-based telescopes. However, no significant detection was achieved in any gamma-ray band (Goldstein et al. 2017; Koccevski et al. 2017; Martinez-Castellanos et al. 2017; Nakahira et al. 2017; Savchenko et al. 2017; Svinkin et al. 2017; Verrecchia et al. 2017; Li et al. 2018). The High Energy Stereoscopic System (H.E.S.S.) array of imaging atmospheric Cherenkov telescopes (IACTs) conducted deep observations in the very-high-energy (VHE;  $E > 50$  GeV) gamma-ray regime, achieving upper limits (U.L.s) in the range of  $0.13 - 23.7$  TeV (Abdalla et al. 2017). Observations were performed with two different cadences: rapid observations from 0.22 to 5.2 days post-merger, and late-time observations 200 days post-merger (Abdalla et al. 2017).

### Chasing Gamma-Ray Signals from Binary Neutron Star Coalescences with the Cherenkov Telescope Array: Prospects and Observing Strategies

Being submitted!

#### Abstract

The detection of gravitational waves (GWs) from a binary neutron star and the identification of its electromagnetic counterparts, heralded the beginning of multi-messenger astronomy. The intensive follow-up campaign contributed to the joint detection of the short GRB 170817A observed by Fermi-GBM, INTEGRAL, together with the VLBI observation of the successful jet, provided the first direct evidence that at least a fraction of BNSs are progenitors of short GRBs. Short GRBs are also expected to emit TeV photons and upper limits have been set with observations performed by ground-based gamma-ray detectors and during the intense electromagnetic follow-up campaign associated with GW170817/GRB 170817A. In the next years, the searches for TeV counterparts will become more effective thanks to the Cherenkov Telescope Array Observatory (CTAO): this instrument will be fundamental for the follow-up of transient GW events at VHE, owing to its unprecedented sensitivity, rapid response and capability to monitor large sky areas via survey-mode operation. The aims of this work are the optimisation of the follow-up strategy with CTAO and a reliable assessment of CTAO capabilities in detecting the TeV emission from GW counterparts in different observing conditions, as well as the evaluation of the expected rate of joint GW-GRB detections with CTAO during Observing run O5. The study presented uses a public, simulated sample of BNS systems, together with the corresponding GW detection during the last inspiraling cycles and merger phase and the 3D sky localisation. The sky position, distance and orientation of the sample of GW-detectable BNSs are used in the subsequent stages. Assuming the correspondence between the BNS merger and the emergence of a short GRB, the gamma-ray emission is simulated using a set of phenomenological prescriptions based on the observed population of short GRBs. The possibility of observing the emission from an off-axis jet is introduced with basic prescriptions on the jet morphology and structure. The response of CTAO to the derived set of spectral and temporal templates is then simulated. The observation with the CTAO is considered with different observing conditions and parameters. The initial uncertainty on the location of the electromagnetic counterpart requires a scan of the GW sky map and hence the definition of a selection strategy of the fields to be observed. Different strategies based on the optimization of a sequence of snapshots with variable and constant integration time are investigated. Among the key results we find that about 3% of simulated GW-associated short gamma-ray bursts produce GeV–TeV radiation detectable by CTAO. Real-time analysis and rapid follow-up are crucial, as the likelihood of detection drops sharply beyond 1–4 hours after the GW event. A 5-minute exposure time per sky tile offers an effective balance between coverage and detection probability. Detectability is strongly influenced by the jet opening angle and viewing angle, suggesting that even rough estimates of the viewing angle in GW alerts could enhance targeting. The simulation framework presented in this work serves as a basis for future studies of scientific scenarios involving GW and gamma-ray signals, including neutron star-black hole mergers, advanced strategies incorporating galaxy distributions, and future detectors such as Einstein Telescope.

Observation optimisation and scheduler  
CTAO observing strategy

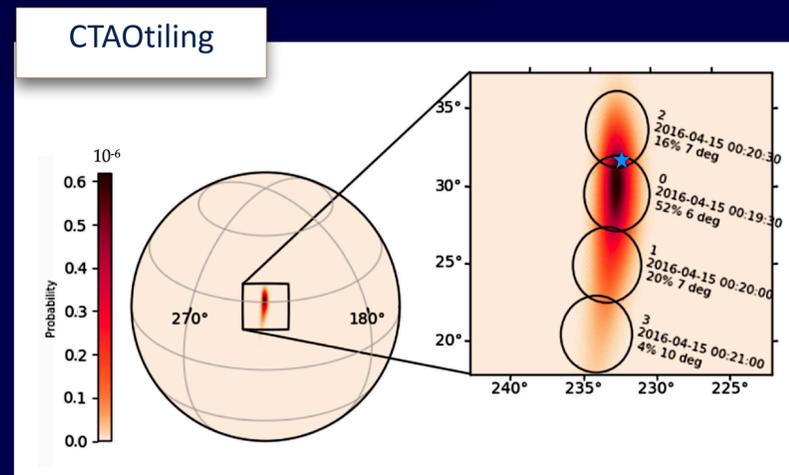

- Realistic observing conditions for CTAO are considered (Seglar-Arroyo et al. 2019)

- Based on Tilepy code (M. Seglar-Arroyo et al. - APJS - 2024)

Observing strategy:

- *Optimal*: Scheduler iterates on the best visible positions, with increasing, sensitivity-dependent, exposures. If the true source position is covered, by construction, it is detected.

- *Fixed*: Tiling with fixed exposures (1, 5, 20 min)

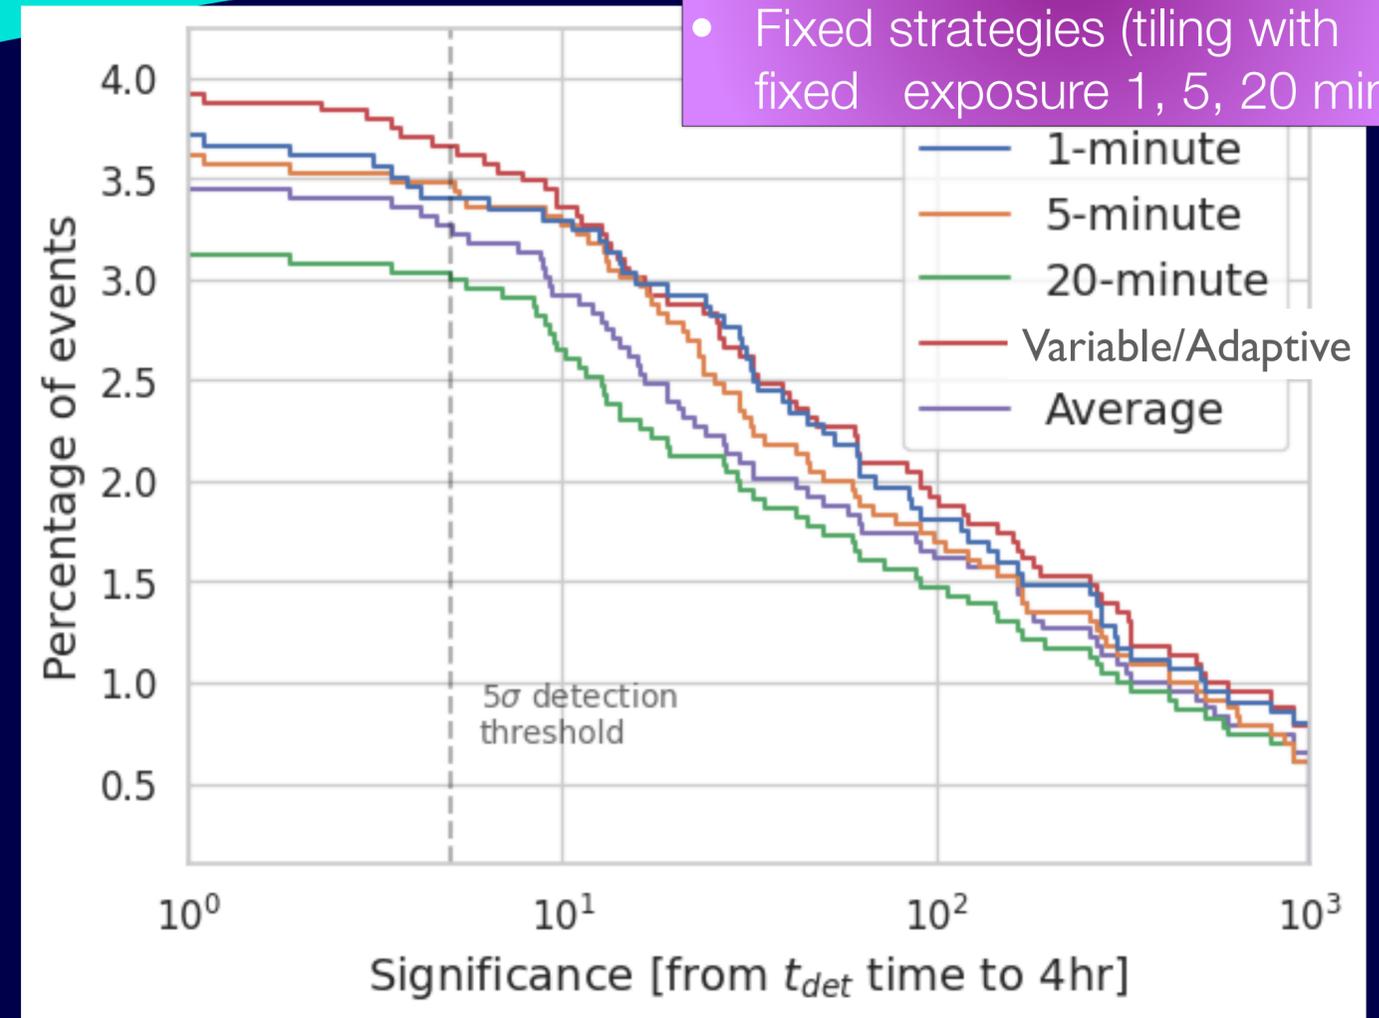

Compute the joint GW and CTAO detection rates from binary neutron star (BNS) mergers associated to GRBs (GW-GRBs)

## Optimise the observing strategy

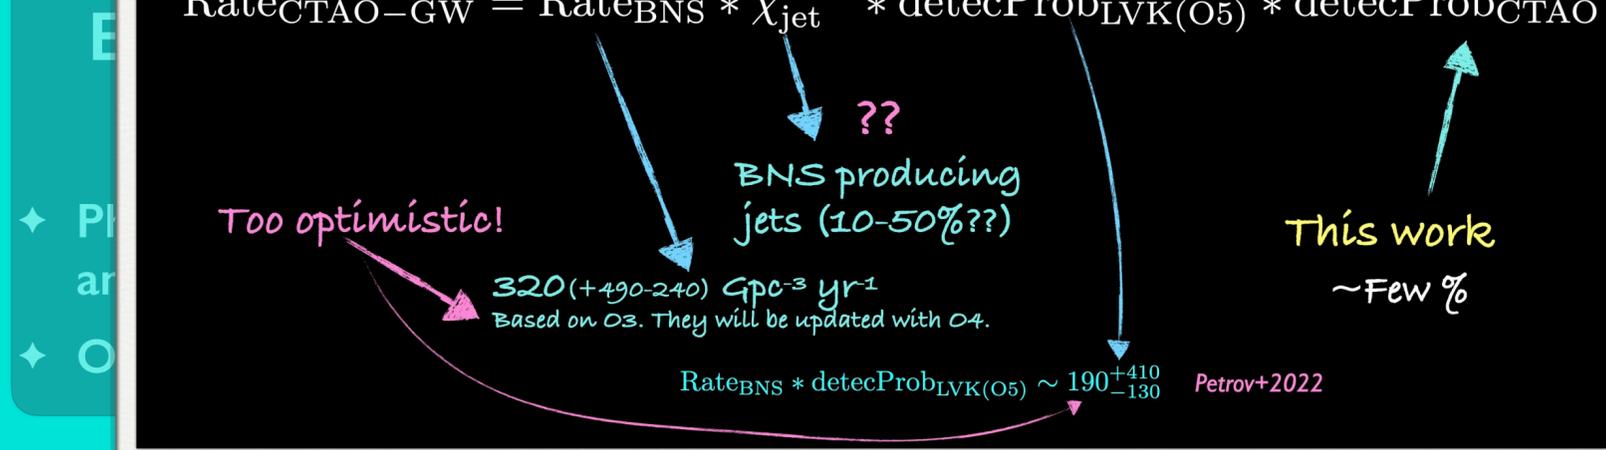

- ◆ Maximise the detection rate
- ◆ Maximise the physical interpretation return
- ◆ Evaluate the amount of observing time

Observing strategies:

- ✓ Optimal (adaptive) exposure
- Fixed strategies (tiling with fixed exposure 1, 5, 20 min)

$$\text{Rate}_{\text{CTAO-GW}} = \text{Rate}_{\text{BNS}} * \chi_{\text{jet}}^{\text{BNS}} * \text{detecProb}_{\text{LVK}(O5)} * \text{detecProb}_{\text{CTAO}}$$

~3-4% of the sampled BNS mergers are detectable. Expected yearly rate depends greatly on the **BNS rate** (largely uncertain!)

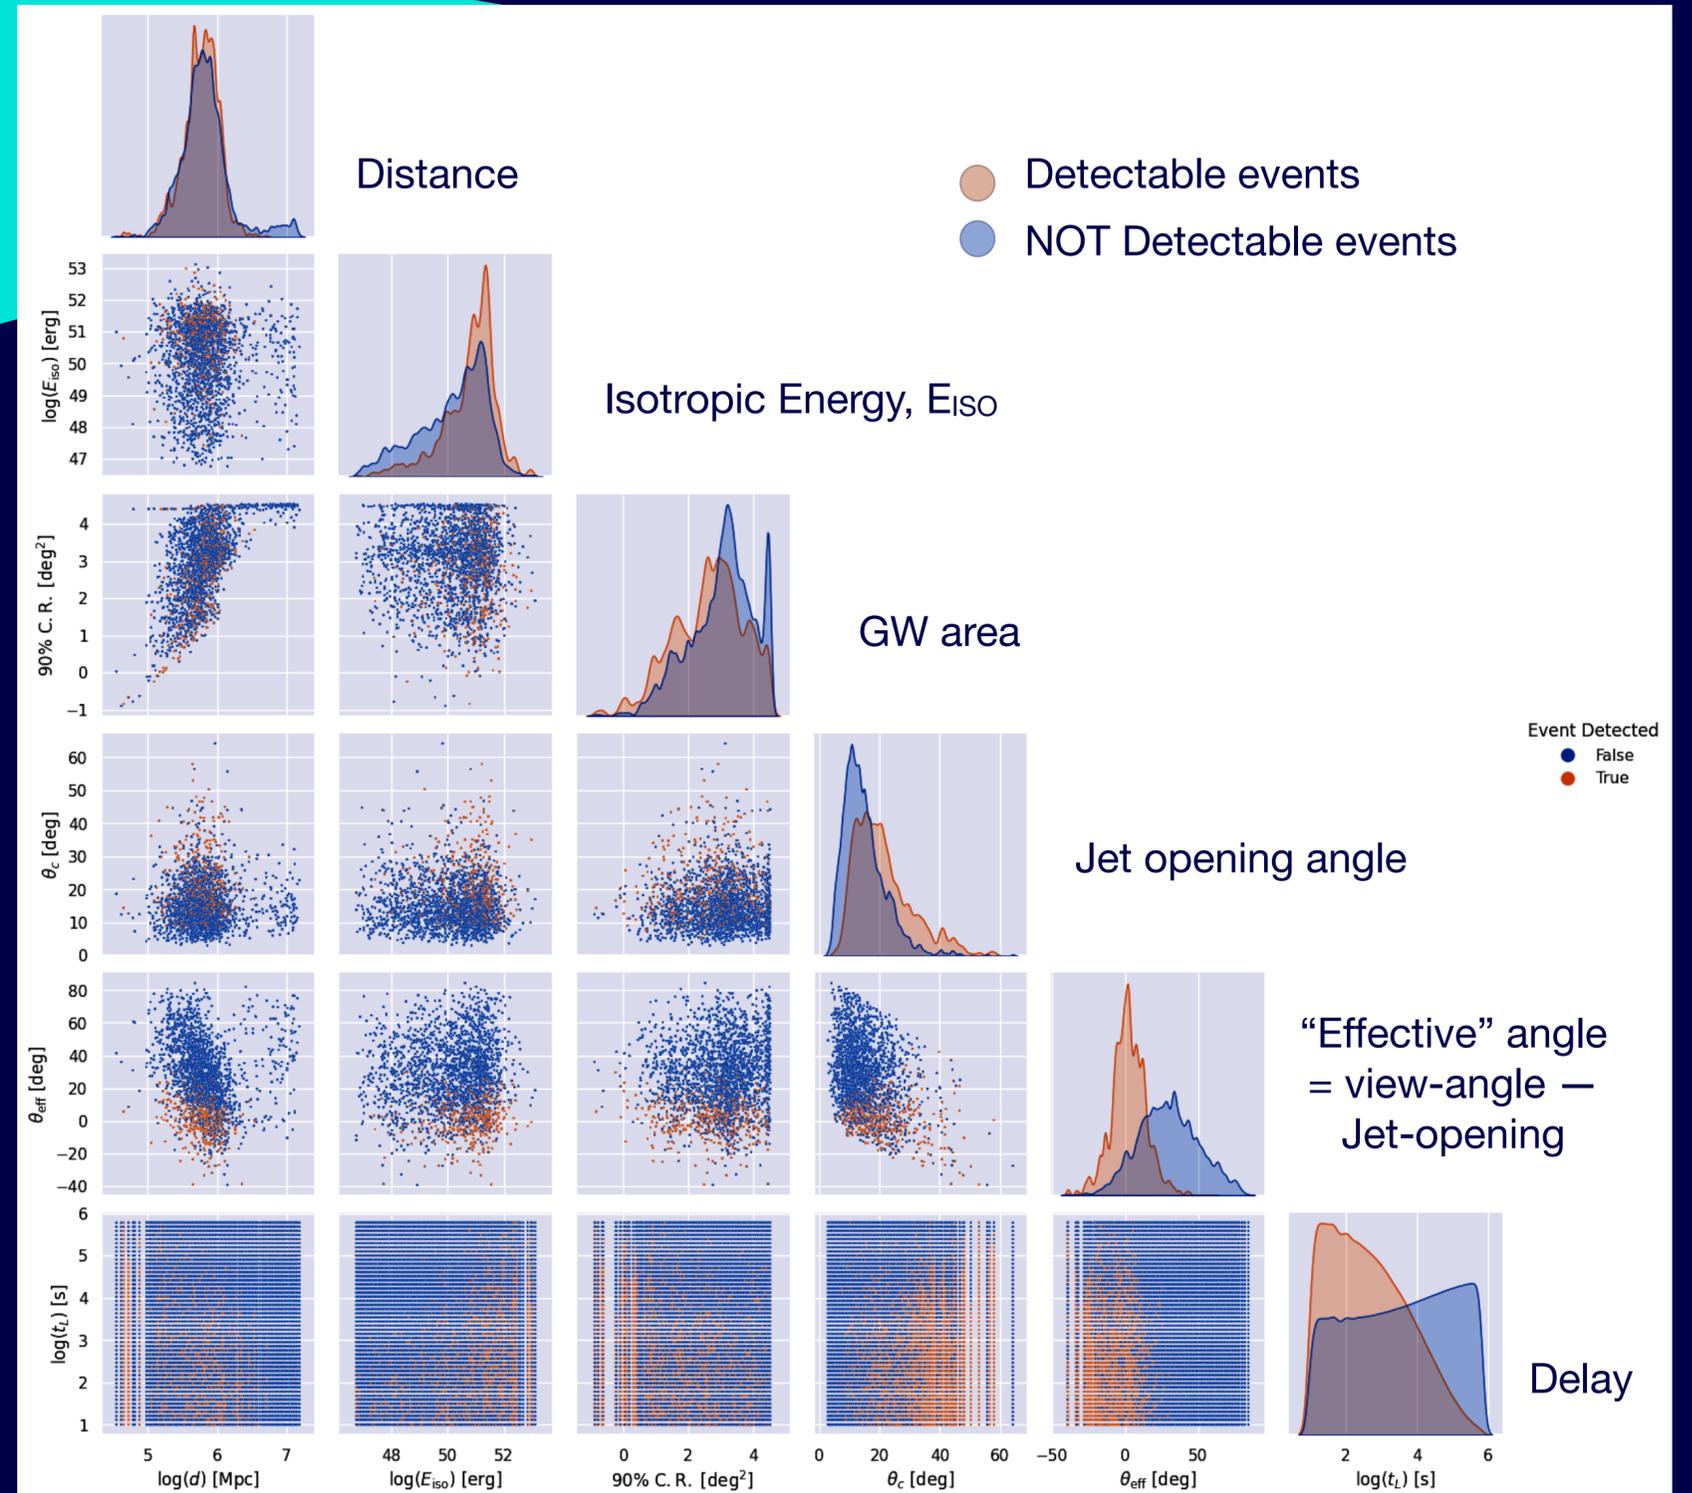

Compute the joint GW and CTAO detection rates from binary neutron star (BNS) mergers associated to GRBs (GW-GRBs)

## Optimise the observing strategy

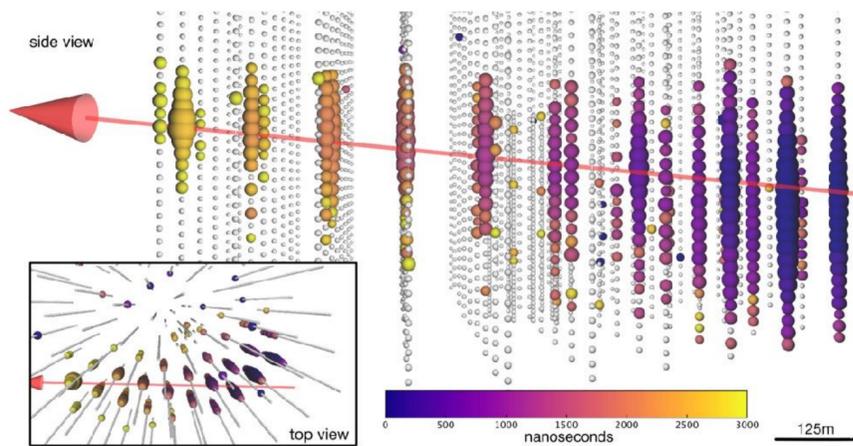

- ◆ Maximise the detection rate
- ◆ Maximise the physical interpretation return
- ◆ Evaluate the amount of observing time

## Explore the parameter space of the GW-GRBs detectable by CTAO

- ◆ Physical parameters (luminosity, jet opening angles and jet orientation) and other (GW area, distance)
- ◆ Observational parameters (time delays, exposures)

- Do all GRB exhibits a second high-energy component (Gev-TeV)? 🥰
- Is this component significant or even dominant, as observed in GRB 190114C and GRB221009A? Under what conditions?
- What is the connection between this emission and the GRB progenitor or its environment?
- Is SSC the dominant emission mechanism? What roles do external Compton, pure synchrotron, or hadronic processes play?
- Next observational breakthrough: unambiguous TeV detection from short-GRB! GW (BNS)! NS-BH and BBH still uncharted territory... (see upcoming LST-Magic paper on followup of 2 BBH events)
- Which observational strategies in the TeV band are best suited for detecting GW counterparts?

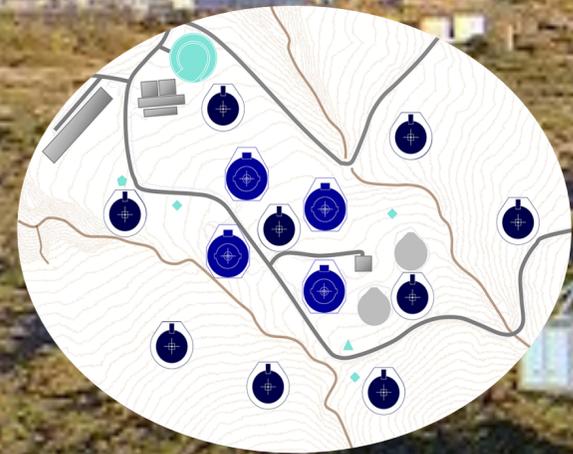

## TeV observations can:

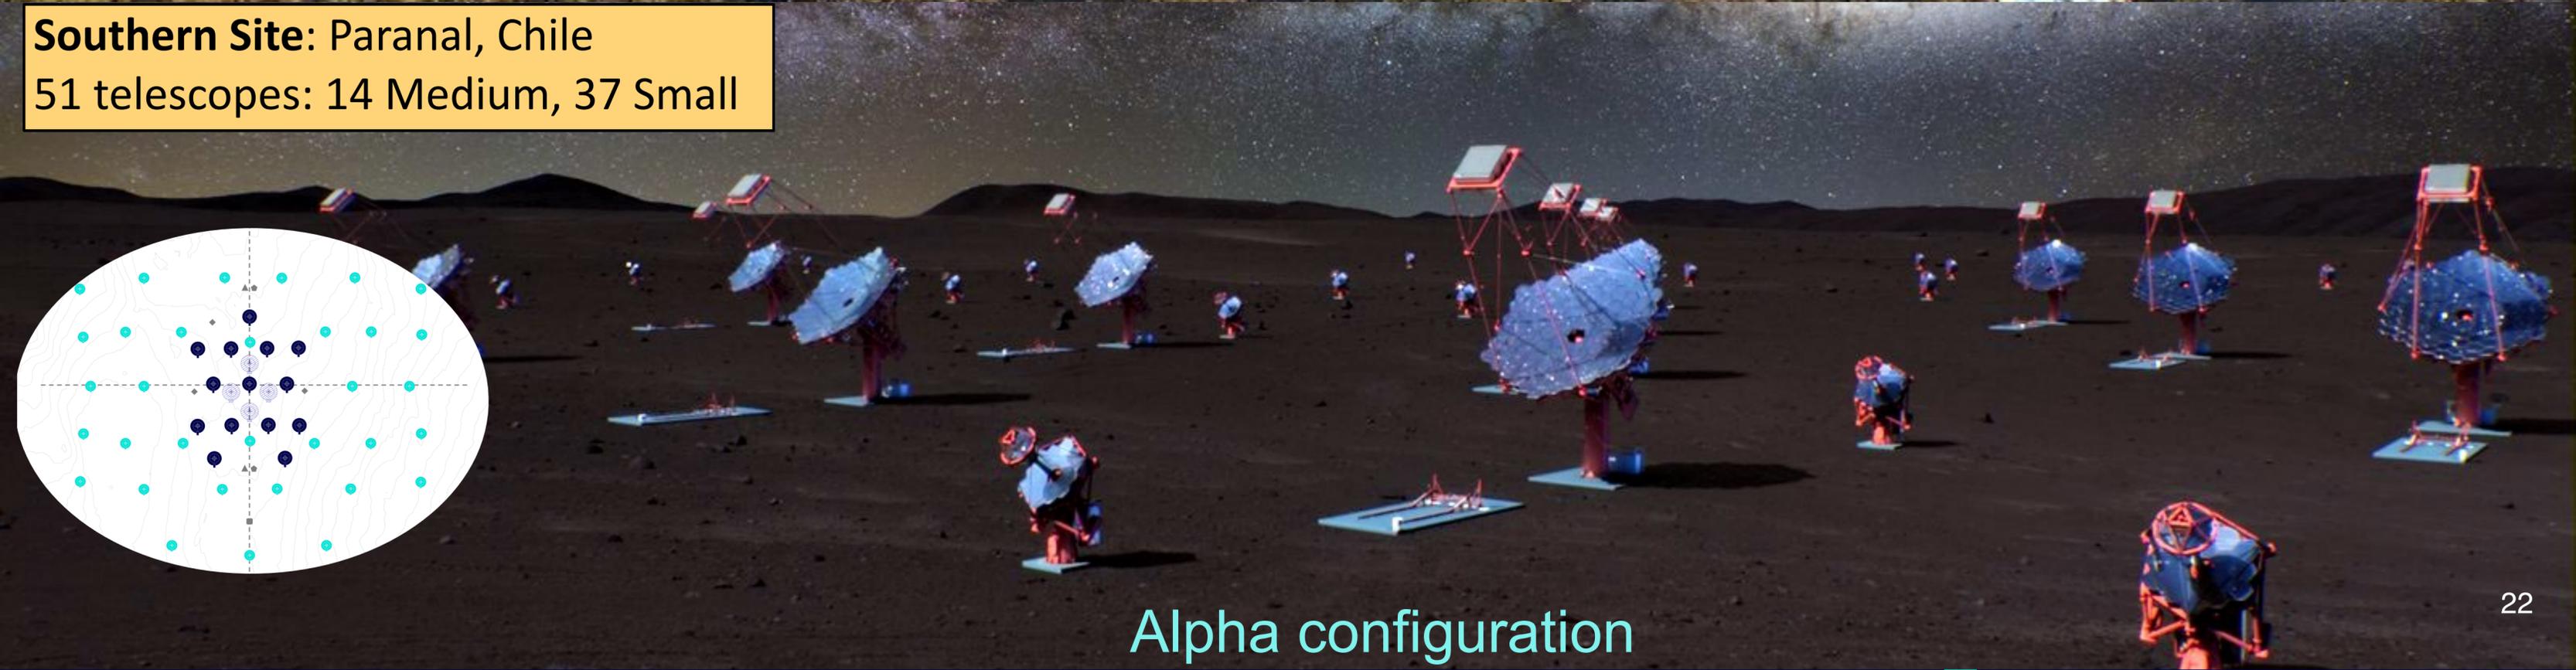

- ✓ Clarify the structure of the environment (density, winds)
- ✓ Better constrain SED modeling and parameters
- ✓ Identify/discard dominant emission processes in afterglow
- ✓ Identify and shed light on the prompt emission physics.

- Which classes of neutrino sources? Seyfert, blazars (BL-Lac? FSRQ?)?
- Which emission region? Corona emission? Base of jet / standing shocks? Outflow winds?
- Confirm the physical connection between neutrino and gamma-ray emission and the interplay with the environment.
- Identify TeV hadronic-driven emission processes in the observed SED
- Which models? How to better constraint their parameters? Needs precision and MWL measurements.
